Synthesis of rare earth doped TiO₂ nanorods as photocatalysts for lignin degradation†

Liang Song,⁎a,b Xueyuan Zhao, a Lixin Cao, c Ji-Won Moon, b Baohua Gu b and Wei Wang⁎b,c

A two-step process is developed to synthesize rare earth doped titania nanorods (RE–TiO₂ NRs) as photocatalysts for efficient degradation of lignin under simulated sunlight irradiation. In this approach, protonated titanate nanotubes with layered structures were first prepared by a hydrothermal approach, and rare earth metal ions were subsequently bound to the negatively charged surface of the synthesized titanate via electrostatic incorporation. The as-synthesized RE–TiO₂ NRs after calcination generally showed much higher photocatalytic efficiencies than those of undoped TiO₂ NRs or the commercial P25 TiO₂ photocatalyst. Using methyl orange (MO) as a probing molecule, we demonstrate that Eu–TiO₂ NRs are among the best for degrading MO, with an observed rate constant of 4.2 × 10−3 s⁻¹. The La³⁺, Sm³⁺, Eu³⁺ and Er³⁺ doped TiO₂ NRs also showed higher photocatalytic efficiencies in degrading MO than the commercial P25 TiO₂. We further demonstrate that lignin can be photodegraded effectively and rapidly at room temperature under simulated sunlight through two reaction routes, which could be important in controlling ways of lignin depolymerization or the formation of reaction products.

Introduction

Lignin, a complex and recalcitrant phenolic macromolecule, is found in most terrestrial plants at approximately 15 to 40% dry weight.¹,² However, this natural macromolecule is resistant to microbial attack and difficult to be degraded biologically due to its complex irregular polymeric structure.² In pulp mills and olive mills, lignin separated from lignocellulose is commonly regarded as pulp black liquor (PBL) and olive mill wastewater (OMW).³–⁵ The chlorination process, which is commonly used to reduce the pollution problems in pulp and paper wastewaters, results in the formation of chlorinated by-products such as polychlorinated biphenyls and chlorophenols.⁶ Photocatalytic degradation is a promising method to directly depolymerize non-biodegradable lignin.⁷ Lignin is one of the most abundant aromatic polymers on earth,⁸ and it is thus of great environmental significance if waste lignin could be converted to renewable chemicals,²,⁹ such as aromatic platform compounds¹⁰,¹¹ and alternative biofuels¹²–¹⁴ through photocatalytic reactions. To achieve this goal, one of the challenges is to develop highly effective photocatalysts to accelerate depolymerization reactions. Recently, one-dimensional titanium dioxide (1D-TiO₂) nanomaterials,¹⁵,¹⁶ such as nanotubes, nanorods and nanowires, have been widely used as photocatalysts¹⁷,¹⁸ owing to their large specific surface area and small dimension effect. However, the catalytic efficiency of pure TiO₂ is relatively low, particularly under visible light irradiation, due to the fast recombination rate of electron–hole pairs in TiO₂. In order to enhance the interfacial charge-transfer efficiency and utilize a wider spectral range of solar energy, the TiO₂ catalyst has been modified by ion doping¹⁹,²⁰ and manipulating the nanomaterial composition.²¹,²² Rare earth (RE) ion dopants, such as Ce,²³ La,²⁴ Er²⁵ and Pr,²⁶ have shown unique enhancement effects, resulting from the orbital hybridization of 4f electrons. Positive effects of 4f electron orbital hybridization on the photocatalytic activities of TiO₂ were reported previously.²⁷,²⁸

In this research, we developed a two-step process to incorporate RE ions (rare earth ions La³⁺, Ce³⁺, Pr³⁺, Sm³⁺, Eu³⁺, Tb³⁺, Er³⁺) into 1D TiO₂ nanostructures and obtained novel RE-doped TiO₂ nanorods (RE–TiO₂ NRs) with narrowed band gap energy and enhanced photocatalytic activity. We determined the photocatalytic efficiencies of the synthesized nanocatalysts through photodegradation of methyl orange (MO) and lignin. Commercial P25 TiO₂ nanocatalyst was used as a reference to evaluate the photocatalytic activities of the synthesized 1D TiO₂ nanocatalysts. To achieve a complete degra-
dation of lignin, previous studies have used oxidizing agents such as H₂O₂ and O₃ to assist the reactions catalyzed by TiO₂. In contrast, we report rapid degradation of lignin in aqueous solution using RE-TiO₂ NRs as photocatalysts without adding any oxidizing agents.

**Experimental**

**Chemicals**

Praseodymium chloride heptahydrate (PrCl₃·7H₂O, 99.99%), samarium chloride hexahydrate (SmCl₃·6H₂O, 99.99%), europium chloride hexahydrate (EuCl₃·6H₂O, 99.9%), terbium chloride hexahydrate (TbCl₃·6H₂O, 99.9%) and erbium chloride hexahydrate (ErCl₃·6H₂O, 99.9%) were purchased from Aldrich. Lanthanum chloride heptahydrate (LaCl₃·7H₂O, assay-LaCl₃ 64.5–78.0%) was obtained from J. T. Baker, and cerium chloride heptahydrate (CeCl₃·7H₂O, 99%) was obtained from Alfa-Aesar. TiO₂ powder (surface area of 40 m² g⁻¹) for synthesis of RE-TiO₂ NRs was obtained from NanoTek. Methyl orange was obtained from Fluka. Alkal lignin (mol wt ~10 000 g mol⁻¹, 4% sulfur impurity) was obtained from Aldrich. Commercial P25 TiO₂ nanocatalyst (average size of 21 nm, surface area of 50 m² g⁻¹) was provided by Evonik Degussa. Deionized (DI) water with a resistance of 18.2 MΩ cm was used in all the experiments.

**Synthesis and characterization of rare earth ion-doped TiO₂ nanorods**

Based on the method developed by Kasuga for synthesis of TiO₂ nanotubes and the electrostatic attraction effect of the negative surface of layered nanotubes, we developed a novel two-step method to synthesize RE-TiO₂ NRs. Briefly, 1.5 g TiO₂ powder was dispersed into 85 mL 10 mol L⁻¹ NaOH solution followed by magnetic stirring for 3 h. The suspension was then transferred into an autoclave lined with Teflon for hydrothermal treatment at 423 K. Upon reaction completion in 24 h, the synthesized sodium titanate nanotubes were separated and thoroughly washed with DI water and a 0.1 mol L⁻¹ HCl solution until the pH value reached ~6.0. The protonated titanate nanotubes were dried at 353 K for use as precursors for the doping procedure. RE ions La³⁺, Ce³⁺, Pr³⁺, Sm³⁺, Eu³⁺, Tb³⁺ or Er³⁺ were mixed with protonated titanate nanotubes at a Ti/RE molar ratio of 20:1 in aqueous solution. The mixture was stirred vigorously for 12 h at room temperature and the nanotubes were separated and dried at 353 K for 12 h to obtain RE-loaded titanate nanotubes. After calcination at 833 K for 4 h, RE-loaded titanate nanotubes were transformed into RE-TiO₂ NRs.

Chemical and structural properties of the synthesized nanomaterials were characterized by Raman spectroscopy (Renishaw micro-Raman system with a NIR laser at 785 nm excitation). Morphologies of the nanostructures were observed by using transmission electron microscopes (Hitachi H-7000, Hitachi HD 2000, 200 kV) with Energy Dispersive X-ray Spectroscopy (EDS). Optical absorption spectra were recorded by using a UV-Vis spectrometer (S. I. Photronics 400 with integrating sphere) in reflectance mode, and BaSO₄ was used as the diffuse reflectance material. Optical upconversion properties were analysed with a fluorescence spectrometer (Jobin-Yvon SPEX Instruments, New Jersey) using a 980 nm laser as the excitation source. Surface charge densities of the as-synthesized 1D nanomaterials were evaluated by zeta (ζ) potential measurements in aqueous suspensions with a dynamic light scattering instrument (Brookhaven 90plus/BI-MAS). The surface area was measured by the BET method using a surface area analyzer (Micromeritics, Gemini VII 2390).

**Results and discussion**

**Formation and characterization of RE-doped TiO₂ nanorods**

A two-step procedure was developed to synthesize the RE-TiO₂ NRs. Step 1 is to prepare 1D titanate nanotubes with layered structures. The layered sodium titanate in the form of hollow nanotubes was obtained by concentrated alkali hydrothermal treatment of titania. In step 2, RE ions were incorporated into the layered nanostructures of titanate nanotubes. For RE incorporation in TiO₂, the incipient impregnation and solvothermal doping method is known to cause precipitation and aggregation of RE ions. Here, the titanate nanotubes were treated with dilute hydrochloric acid for exchanging sodium ions with protons, and RE ions were thus homogeneously bound to the negatively charged surface of the nanotubes via electrostatic interactions.

TEM images of the synthesized 1D nanomaterials are shown in Fig. 1. The protonated titanate nanotubes showed a layered structure and the selected area electron diffraction (SAED) pattern (Fig. 1a and inset) indicated their poor crystallinity, which is consistent with XRD patterns (Fig. S1). Protonated titanate nanotubes exhibited vibrational bands at 283,
451, and 661 cm$^{-1}$, as shown in the Raman spectrum (Fig. S1b†), which are assigned to Ti-O-Ti vibration from 2D lepidocrocite-type TiO$_6$ layers. The band at 824 cm$^{-1}$ is due to a covalent Ti–O–H bond,\textsuperscript{35} implying that the protonated titanate nanotubes have a monoclinic crystal structure of the tritiitanate (H$_2$Ti$_3$O$_7$) phase.\textsuperscript{35–37} After calcination at 833 K, the protonated titanate nanotubes were dehydrated and converted into TiO$_2$. The HRTEM image (Fig. 1b and inset) indicates that the morphology of 1D nanomaterials was transformed to nanorod-like multilayered structures with high crystallinity. The interlamellar spacing of the undoped layered TiO$_2$ nanorods was 0.72 nm. Doping of RE ions into the layered titanate nanotubes did not affect the rod-like morphology (Fig. 1c). After the same calcination treatment, the RE–TiO$_2$ NRs showed similar nanostructures to the undoped TiO$_2$ NRs. The average diameters of the RE ion doped nanorods are about 8–12 nm.

The surface charge density of the synthesized titanium based 1D nanomaterials was evaluated by zeta potential measurements. The results revealed that the layered protonated titanate nanotubes were negatively charged ($\zeta = -31$ mV) while highly crystalline TiO$_2$ nanorods became positively charged ($\zeta = +2$ mV) at the pH value of 6.8. The layered nanotubes with a high BET surface area ($\sim 340$ m$^2$ g$^{-1}$) provided a large number of adsorption sites for RE cations. Owing to the lamellar spacing of titanate precursors, rare earth metal ions (e.g. ionic diameters, La$^{3+}$ of 1.061 Å, Sm$^{3+}$ of 0.964 Å, Er$^{3+}$ of 0.881 Å) facilely diffused into the adsorption sites between interlayers, and homogeneously grafted onto the negatively charged surface of the titanate nanotubes through electrostatic interactions. The negatively charged and layered surface of titanate nanotubes is crucial to prevent aggregation of RE ions in the calcination treatment.

To evaluate the doping status of RE ions, the synthesized RE–TiO$_2$ NRs were examined by Raman spectroscopy (Fig. 2). After calcination at 833 K, RE–TiO$_2$ NRs exhibited characteristics of the anatase phase with typical Raman bands centered at 638, 515, and 395 cm$^{-1}$ for Eg, A$_{1g}$/B$_{1g}$ and B$_{1g}$ vibrational modes, respectively. No rutile phase or rare earth oxide phase was observed in the Raman spectra of RE–TiO$_2$ NRs. The Raman shift is very sensitive to lattice distortion by dopants. The redshift of the Eg mode (located at 638 cm$^{-1}$) was observed for the RE ion doped nanorods, indicating lattice disorder and oxygen deficiencies derived from RE ion doping. A similar phenomenon was observed in the doped 3D-TiO$_2$ nanomaterials.\textsuperscript{39,40} Since Raman peaks usually become weak and broad when the samples have local lattice imperfections,\textsuperscript{39} full width at half maximum (FWHM) of the vibrational bands was calculated using a Lorentzian peak function. The FWHMs of the Eg peak were 22.8 ± 0.7 cm$^{-1}$ and 28.4 ± 0.7 cm$^{-1}$ for the undoped and doped nanorods, respectively (Table 1). The FWHMs of A$_{1g}$ and B$_{1g}$ peaks also increased slightly after doping. The Raman peaks of the doped samples broadened with respect to FWHM, implying lattice distortion induced by the RE dopants.

Trace amounts of RE ions were detected by EDS, as shown in Fig. S2† though the RE-O bonds were not detected by Raman spectra. However, EDS results could not reveal whether the RE ions were chemically bonded into the TiO$_2$ lattice. In order to verify this, we measured upconversion fluorescence of Er and Yb co-doped TiO$_2$ NRs synthesized by using the same procedure, because the upconversion fluorescence derives from the RE ions being chemically bonded into the lattice.
from the high levels of homogeneously distributed doping in the host lattice and the avoidance of radiationless electronic decay pathways for the excited RE dopant ions. With excitation at 980 nm, emission was clearly observed at 524, 553 and 660 nm for the Er and Yb codoped TiO$_2$ NRs, which confirmed that the RE ions were chemically incorporated into the lattice of TiO$_2$ (Fig. S3†).

Reflectance spectra of the RE–TiO$_2$ NRs were investigated in the spectral range of 350–800 nm, as shown in Fig. 3 and S4†. We observed that the TiO$_2$ NRs had no absorption in the visible light region because of their relatively high bandgap energy, while the RE–TiO$_2$ NRs caused a red shift, especially for the Ce- and Tb-doped TiO$_2$ NRs. The absorption spectra of the Pr, Sm, Eu, or Er doped NRs were observed between spectra of the La–TiO$_2$ and the Tb–TiO$_2$.

Bandgap energies of the undoped TiO$_2$ and the RE doped TiO$_2$ were estimated according to the reflectance spectra. The bandgaps of RE doped TiO$_2$ NRs were narrow compared with that of the undoped TiO$_2$ NRs, as shown in Table 2. These results are in agreement with the literature report on RE ion doped 3D TiO$_2$. The presence of RE ions (4f electrons) in the TiO$_2$ matrix induced the RE impurity energy level between the O 2p orbital and Ti 3d orbital, which narrowed the charge transfer band.$^{44}$

**Evaluation of photocatalytic efficiency**

We used methyl orange (Fig. S6a†), a representative azo dye, as a model pollutant to evaluate the photocatalytic efficiencies of the synthesized RE–TiO$_2$ NRs. As shown in Fig. 4, the RE–TiO$_2$ NRs calcined at 833 K showed the highest photocatalytic activity. Because the RE–TiO$_2$ NRs treated at 833 K have a higher crystallinity than those calcined at lower temperatures, these results indicate that the crystallinity of Ti-based 1D catalysts is one of the key factors affecting the photocatalytic performance.

Control experiments showed that there was no degradation of MO in the absence of photocatalysts (Fig. S5†). Commercial P25 TiO$_2$ was commonly used as a standard photocatalyst for estimating the photocatalytic activities of aromatic molecules.$^{48,49}$ Here the kinetic processes of degradation of MO were also compared in the presence of the photocatalysts P25 TiO$_2$ and RE–TiO$_2$ NRs by presenting $-\ln(C/C_0)$ vs. $t$ plots in

Photocatalytic degradation of lignin

As a recalcitrant phenolic macromolecule, lignin (Fig. 6b and c†) is resistant to be degraded in natural environments, due to its highly irregular polymeric structure.² As shown in Fig. S7, lignin is hard to be degraded under UV-Vis light irradiation without catalysts. The photochemical reaction of lignin is a slow and complex process.⁵¹,⁵²

In our experiments, photocatalytic degradation of lignin was studied at 100 mg L⁻¹ at pH 7.0 in the presence of RE-TiO₂ NRs in solution. UV-Vis absorption spectra and IR spectra are usually employed to evaluate the decay process of water soluble lignin.⁵² The photodegradation process of lignin with Sm-TiO₂ under simulated sunlight irradiation is illustrated in Fig. 6. UV absorption peaks of lignin were observed at 279 nm (~100 kcal mol⁻¹) and 201 nm (~140 kcal mol⁻¹). The strong absorption at 201 nm is assigned to the π → π* electronic transition of aromatics.⁵³ Absorption at 279 nm is attributed to the hydroxyl groups or etherified hydroxyl groups in lignin units, which is assigned to n → π* electronic transitions. The symbol “n” is non-bonding electrons, which correspond to the lone electron pairs of the –O– ether bond and the –OH hydroxy bond.

In the absence of the catalyst, there is little degradation of aromatics, as indicated by the UV absorption peak at 201 nm (Fig. 7). The absorption peak at 279 nm, representing oxygenated groups of lignin, did not show any noticeable changes

either (Fig. 8). This is attributed to the stability of the conjugated aryl groups and oxygenated structures, such as the hydroxyl group and the methoxy group in lignin monomers, which are hard to break down.

The absorption peak at 201 nm decreased consistently over time using the synthesized RE-TiO$_2$ NRs as the photocatalyst. However, with the Pr$^{3+}$, Ce$^{3+}$, and Eu$^{3+}$ ion doped TiO$_2$ NRs as photocatalysts, we found that the peak value at 279 nm first increased and then decreased over time (Fig. 8). This observation is similar to that found in the degradation of lignin dimer model compounds. The Sm$^{3+}$, La$^{3+}$, Er$^{3+}$, Tb$^{3+}$, and Pr$^{3+}$ ion doped TiO$_2$ NRs were more effective than the standard catalyst P25 TiO$_2$. Unlike the degradation of the dye with the azo group ($-\text{N=N}-$), the Ce$^{3+}$, Tb$^{3+}$ and Pr$^{3+}$ ion-doped TiO$_2$ NRs showed enhanced reactivities for photocatalytic degradation of aromatics.

### Reaction routes of photocatalytic depolymerization of lignin

When using Sm$^{3+}$, Er$^{3+}$, La$^{3+}$ and Tb$^{3+}$ ion-doped TiO$_2$ NRs as photocatalysts, the UV absorbance at both 201 nm and 279 nm decreased, suggesting photodegradation of the lignin aromatic structures. However, the peak intensity at 279 nm increased at the initial stage, when the Eu$^{3+}$, Ce$^{3+}$, and Pr$^{3+}$ ion doped TiO$_2$ NRs were used. The initial increase in UV absorbance at 279 nm was generated from the decay of oxygen bonds (e.g., phenolic hydroxyl groups, phenolic methoxyl groups and alkylaryl ether bonds). These results pointed out that there were two photocatalytic degradation routes of lignin over different RE doped TiO$_2$ nanocatalysts.

FTIR spectroscopy was used to investigate the functional groups or chemical bonds of lignin. The most representative vibrational bands and their assignment in the spectral range of 1600-1200 cm$^{-1}$ (Fig. 9 and 10) are summarized in Table S1.

- The bands at 1596 and 1504 cm$^{-1}$ are due to C=C stretching of the aromatic skeletal vibrations.
- The bands at 1464 and 1425 cm$^{-1}$ are assigned to C–H deformations in methyl, methylene and methoxyl groups in lignin.
- The bands between 1270 and 1200 cm$^{-1}$ are due to C–O and C–O–C stretching in lignin.

Significant spectral changes can be observed in the fingerprint region during photocatalytic reactions for all samples. The degradation of lignin was reflected...
Conclusions

A facile two-step process, utilizing electrostatic incorporation between positively charged rare earth ions and negatively charged titanate nanotubes, is presented as an alternative route to synthesize RE-doped TiO$_2$ NRs. The structure and morphology of the synthesized nanomaterials were characterized by TEM, Raman scattering and up-conversion fluorescence spectroscopy. The as-synthesized La$^{3+}$, Sm$^{3+}$, Eu$^{3+}$ and Er$^{3+}$ doped TiO$_2$ catalysts showed enhanced photocatalytic efficiency in degrading azo dye compounds such as MO. The Eu–TiO$_2$ NRs showed the highest reaction rate (42 × 10$^{-4}$ s$^{-1}$) with MO. Lignin could be photodegraded completely using the as-synthesized RE–TiO$_2$ NR catalysts under simulated sunlight. We also found that photodegradation of lignin can proceed through two different routes by forming different intermediate products, suggesting the possibility of controllable ways of lignin depolymerization.
